Objectives: This study introduces an initial evaluation of a novel High-Intensity Focused Electromagnetic (HIFEM) technology. The primary goal is to quantify any effects the treatments may have on abdominal tissues, as well as to establish hypotheses for future research of this technology.

Methods: Twenty-two patients received four abdominal treatments using the EMSCULPT device (BTL Industries Inc., Boston, MA). Anthropometric evaluations were recorded and digital photographs were taken at baseline, at 2 months, and at 6 months post-treatments. The MRI without contrast determined by vertebrae T12 and S1 (FIESTA and FSPRG sequences) was used to measure dimensions in coronal cross-sectional images of abdominal muscle and fatty tissues, in order to assess any anatomical changes induced by the application.

Results: Analysis of the same MRI slices verified by tissue artefacts showed a statistically significant (all \(P < 0.0001\)) average 18.6% reduction of adipose tissue thickness, 15.4% increase in rectus abdominis muscle thickness, and 10.4% reduction in rectus abdominus separation (diastasis recti) as measured from the medial border of the muscle 2 months post-treatment. More significant improvements were observed in patients with BMI 18.5–24.9 (classified as “normal”). MRI data from 6-month follow-up suggest the changes can be preserved in longer term. Tape measurements showed on average 3.8 cm subumbilical circumference reduction. The weight of the subjects did not change significantly (average −0.5 lb; \(P > 0.05\)). No adverse events were reported.

Conclusions: MRI, considered as a highly precise diagnostic method, revealed simultaneous muscle growth, fat reduction and reduced abdominal separation at 2 months and at 6 months post treatments, unrelated with dieting. Further research should investigate the exact physiological processes which stand behind the tissue changes observed in this study. Lasers Surg. Med. © 2018 The Authors. INTRODUCTION

The popularity of non-invasive body shaping procedures has been growing rapidly—the number of procedures performed in the US more than doubled between 2012 and 2016 [1]. Cryolipolysis, radiofrequency, low level laser therapy and focused ultrasound [2] are most widely used for treating patients’ fat bulges, and their efficacy has been demonstrated in multiple previous studies. Similar to every aesthetic procedure, these technologies have also certain limitations. All current non-invasive fat removal treatments are based on thermal effects and as such, they may bring about various cold or heat related side effects. More importantly, all these modalities are designed to address only fat tissue.

Subcutaneous fat is an important factor affecting patient’s body contours as it comprises approximately 25% [3] of human body composition. However, muscle tissue comprises even a larger portion of the human body composition (42% male/36% female [4]) and depending on individual characteristics, the condition of patient’s muscle can play either an equal or even more important role in defining the overall aesthetic appearance. Still, physical workout is currently the only generally available method for natural strengthening of one’s muscles.

The use of magnetic stimulation has a proven track record when treating various medical indications, ranging from neurology [5–7], psychiatry [8], physiotherapy [9–12], to treating urinary incontinence in women [13]. Furthermore, due to the non-thermal and non-ionizing nature of...
the technology, its application is considered relatively safe [8]. Even though the technology is highly effective, it is not as widely used as electrical stimulation [14].

This study brings an initial evaluation of a novel High-Intensity Focused Electro-Magnetic (HIFEM) technology applied to the abdominal area, in order to assess the physiological response in treated patients. The primary goal is to quantify any effects the treatments may have on abdominal tissues, as well as to establish hypotheses for future research of this technology. The outcomes of the study are expected to suggest if HIFEM can be potentially used as a new technology for non-invasive body shaping treatments.

MATERIALS AND METHODS

Study Population

Twenty-two subjects (10 females and 12 males) participated in this prospective, multi-center, non-randomized, pilot study. The average age of the participants was 39.4 ± 10.2 with a mean BMI prior to the treatments of 25.7 ± 2.4 kg/m². The exclusion criteria included pregnancy, breastfeeding, any medical condition contraindicating the application of an electromagnetic field, heart disorders, unhealed wound in abdominal area, and any concomitant medication known to cause bloating or affect weight. See Table 1 for the baseline demographic profile. Patients were not financially incentivized for either participation or completion of the study; an informed consent was obtained from all of them. The study was conducted in compliance with applicable ethical standards and used an IRB approved protocol.

Study Design

Prior to the treatments, each subject was inquired about his/her physical activity habits and an approximate daily caloric intake was calculated in cooperation with a professional nutritionist. All patients were asked to maintain their routine diet and activity level without any modifications until study completion. Afterwards, patients received four treatments (spaced by 2–5 days) using a HIFEM technology device (EMSCULPT, BTL Industries, Boston, MA) as per the IRB-approved protocol.

EMSCULPT Procedure

During the application, patients did not receive any anesthesia and were lying in a supine position. All procedures were applied to the abdomen and each session included exactly 30 minutes of continuous application. One applicator (see Fig. 1) was placed on the skin at the umbilical level. The center of the magnetic coil was placed exactly above the navel. The applicator was affixed by a disinfected fixation belt to minimize movements during the procedure. The stimulation intensity started at 0% and within 60 seconds to the treatment it was slowly increased by the operator until reaching patient’s tolerance threshold. The tolerance threshold was continuously challenged during the course of the treatments. A dual feedback principle was applied, with the operator visually checking the intensity and homogeneity of the muscle contractions across the abdomen, as well as regularly asking the patient about feedback regarding the level of comfort and the balance of contractions between different abdominal areas.

Evaluation Methodology

A complete evaluation of the patients was performed at baseline and 2 months after their last treatment, and included a brief medical history and examination, magnetic resonance imaging (MRI) scan, weight and waist circumference measurements, digital photography, and monitoring of any adverse events. Due to financial constraints, only four randomly selected patients were scheduled for a 6-month follow-up to gain an insight into the tendencies the result may have in the long term. MRI scans were used to observe changes in abdominal fat and muscle tissues of the treated patients. The scanned body volume was defined by T12 and S1 vertebrae and the array coil system was set up in such a way to minimize any pressure on patient’s torso. The images were acquired using the BH-Ax-T2-FIESTA and BH-Ax-T1-FSPGR sequences. For each patient, lateral subumbilical and

MRI Evaluation of Abdominal Tissues

The study average and individual patient changes in abdominal fat, abdominal muscle and diastasis are presented in Table 2 and Figure 2, respectively. On average a statistically significant improvement was observed in all three measurements when comparing the 2-month follow-up to the baseline—a reduction in adipose tissue thickness (−18.6%), an increase in rectus abdominis thickness (+15.4%) and a reduction in abdominal separation (−10.4%). In total 91% (n = 20) of patients improved in all three facets simultaneously. The analysis did not show any non-responding patients who would not have any changes in the tissue at all. No other structural changes in the tissues were observed.

An increase in the abdominal muscle mass was observed in 95% (n = 21) of patients; one subject did not show any change. The muscle growth was relatively consistent, with majority of patients showing an increase in the range of 10–20% (see Fig. 3). The changes were calculated across both sides of the muscle; the difference in growth between the right and left rectus abdominis was insignificant. However, the distance (separation) between the left and right abdominal muscles decreased in 91% (n = 20) of patients; one patient did not show any change and for another patient the distance marginally increased (+0.26 mm or +2.4%). Contrary to our expectations, a subgroup of women who had previously been pregnant (n = 9) did not have higher values of abdominal separation before treatments (average 14.9 mm compared to 17.8 mm in other patients). They however did trend toward slightly greater proportional improvement (average reduction was 11.0% compared to 10.0% in the rest of the cohort). The percentage change in abdominal separation was independent of its severity (size) before treatments. Also, statistical analysis confirmed that the changes in muscle thickness and changes in abdominal separation were two highly independent effects (P > 0.05; correlation coefficient −0.31). MRI of subjects with major muscle growth thus did not necessarily reveal a major reduction in abdominal separation.

Measurements of the fat tissue revealed an opposite trend, with the average thickness decreasing in all patients. The reduction was slightly more variable than changes in the muscle (coefficient of var. 58.1%); this was primarily driven by two positive extremities. In total 82% (n = 18) of patients had the fat layer reduced by more than 10% at the follow-up. More significant absolute changes were observed in subumbilical MRI cuts opposed to epiumbilical cuts.

For both the reduction in fat and reduction in abdominal separation, slightly more significant improvements were seen in patients with BMI classified as “normal” (18.5–
24.9 kg/m²). Their subcutaneous fat mass decreased on average by 20.6%, and the size of diastasis decreased by 11.7%. For “overweight” patients (25.0–29.9 kg/m²) the same measurements averaged 18.1% and 10.0%, respectively.

6-Month Data

Based on MRI evaluation, the muscle thickness continued to grow and the abdominal separation continued to shorten in all four randomly selected patients when compared to the 2-month follow-up. The average thickness in these patients evolved from 9.67 mm (baseline), to 11.38 mm (17.7% increase at 2 months), and on to 11.65 mm (20.5% increase at 6 months). The abdominal separation further improved from average of 12.95 mm (2 months) to 11.18 mm (6 months). In the same patients, the average thickness of subcutaneous fat was on average 3.03 mm lower (22.69 mm) at 6 months compared to the baseline (25.72 mm), see Figure 4.

Other Evaluation

Compared to the baseline, the average subumbilical circumference of patients decreased by 3.8 ± 2.1 cm at the 2-month follow-up. The change was statistically independent of weight variations; the average weight remained stable. Digital photographs showed distinctive aesthetic
improvements in all patients except for one. Examples of digital photographs linked with corresponding MRI images are shown in Figures 5 and 6.

**DISCUSSION**

The findings from MRI scans presented herein have shown that application of the HIFEM technology on the abdomen can cause three different simultaneous changes in abdominal tissues non-invasively. Visual improvement in patients’ appearance observed 2 months after their last treatment very much resemble the effects of non-invasive heat or cold-based fat reduction treatments combined with an extremely intensive physical workout.

The majority of therapeutic approaches aim at reducing the subcutaneous fat layer (either surgically or non-invasively), yet none of the previous ones deal with strengthening of the muscular foundations. Currently, the only way to strengthen the core is a physical workout plan. The investigated device uses HIFEM technology to induce almost 20 thousand pulses in one 30-minute session. Such frequency of nerve stimuli leads to supramaximal muscle contractions which are not achievable voluntarily. The muscle tissue is forced to adapt to this stress, resulting in muscle thickening. The principle of muscle hypertrophy and hyperplasia induced by intensive muscle contractions has already been proven in previous studies [15–19]. The 6 month data suggest that the muscles continue to improve in longer term, both in terms of their overall mass and lateral separation, yet further investigation is necessary to better understand the exact physiology.

Research on high intensity muscle training has shown that a lipolytic reaction takes place in fat tissue adjacent to the contracting muscle [20]. The MRI scans presented herein show a reduction in adipose tissue not immediately after the treatments, but 2 months after the last procedure. A possible explanation for the lasting reduction in fat is that the lipolytic reaction is so intense, releasing large amount of free fatty acids (FFA) which intoxicate the adipocytes and trigger their death. This cell reaction has already been shown in multiple studies in other fields of medicine [21–24]. A recent histology study reported a significant increase in the apoptotic index of adipocytes after one HIFEM treatment on pigs (Weiss R, presented at ASLMS, Dallas TX, April 2018). Their observation was coupled with an increased presence of mRNA pro-apoptotic markers in molecular biochemistry results, as well as with an increased concentration of FFA in blood serum. In addition, an increase of 91.7% (from 18.8 to 35.9) in the apoptotic index was calculated from 120 histological

**Fig. 5.** Magnetic resonance and digital images of Subject ID2 before (left) and 2 months post-treatments (right). Male (30), BMI 24.8 kg/m² (before) and 24.5 kg/m² (2 months), weight −2.2 lb (−1.2 %), subcutaneous fat −30.3% (white markings), muscle thickness +13.7% (green markings), abdominal separation −24.9% (red markings), circumference −3 cm. Combination of the effects produced an overall visual improvement in patient’s abdominal area.
samples. This again suggests a potential relationship between FFA released after the muscle contractions and fat apoptosis, however this hypothesis requires further research as its validation was not the purpose of our study.

The third major observation, a reduction in abdominal separation, was rather variable. An 84.8% coefficient of variation shows that the response in patients differed significantly, from very little change to more dramatic reduction in the muscle distance. At the baseline, only one patient suffered from actual diastasis recti as per the medical definition (i.e., gap >2.7 cm) [25]. Still 91% of subjects showed an improvement. This suggests that the application can not only help severely affected individuals, but is effective on most individuals regardless of their condition. This concept of reducing abdominal separation by using a magnetic field technology would deserve further investigation. In addition, there may be some role in prevention by intervention prior to reaching the medical definition of diastasis, although this would deserve further study as well.

Although the sample is not large enough for a detailed statistical analysis of fragmented sub-groups, the data indicate that neither gender nor age affect the outcomes of the treatments. The fact that slightly more significant changes in abdominal tissues were observed in thinner rather than overweight patients can most likely be attributed to the intensity of the magnetic field which decreases with an increasing distance from the actual magnetic coil. For higher BMI patients, the distance between the coil and the motor neurons responsive to the current will tend to be much larger due to the interspacing fat deposits. Such patients might not achieve as intensive muscle contractions compared to normal BMI individuals. Despite the fact that inductive effects of HIFEM taper with distance, they can be felt from a distance of more than 7 cm from the actual applicator. Data from our study suggest that ideal candidates might be patients with less than an inch (2.5 cm) of a pinchable subcutaneous fat. Our 6-month data suggest the tissue changes may last. However, due to the absence of any guidance in the literature on performing longer follow-up studies, 4 to 6 months seem to be a reasonable time window for re-invitation of patients to assess if any additional procedures may or may not be beneficial.

**CONCLUSION**

The aim of this study was not to establish conclusive evidence for the efficacy of the investigated device. To the best of our knowledge, no peer-reviewed study has investigated a potential use of the HIFEM technology for non-invasive body shaping. The data presented herein show an initial evaluation on 22 patients, and suggest possible physiological responses of the human body to the treatments. We may well conclude that the results have established a hypothesis of three simultaneous abdominal tissue effects induced as a direct result of the treatments, yet additional research is necessary to validate this in a larger controlled study, as well as in a histological study.

Fig. 6. Magnetic resonance and digital images of Subject ID16 before (left) and 2 months post-treatment (right). Female (52), BMI 25.1 kg/m$^2$ (before) and 24.4 kg/m$^2$ (2 months), weight −4.4 lb (−2.9%), subcutaneous fat −32.9%, muscle thickness +19.4%, abdominal separation −15.9%, circumference −5.7 cm. Combination of the effects produced an overall visual improvement in patient’s abdominal area.
that would help further cast light on the exact mechanism of action that would explain our observations. If confirmed, the technology would represent a completely new approach to non-invasive body shaping, bringing the additional muscle effects to the already established fat removal market.
